detector at the PEP-II factory at SLAC. We observe a peak in the photon energy spectrum at energy corresponds to an mass splitting is with a significance of 10 standard deviations. We interpret the observed peak as being due to monochromatic photons from the radiative transition: 

\[ E_{\gamma} = 921.2^{+2.4}_{-2.1}(\text{stat}) \pm 2.4(\text{syst}) \text{ MeV} \]

The branching fraction for this is estimated to be \( [4.8 \pm 0.5(\text{stat}) \pm 1.2(\text{syst})] \times 10^{-4} \).
Thirty years after the discovery of the narrow Y(nS) resonances [1], no evidence has been reported for the spin-singlet pseudoscalar partners \( \eta_s(nS) \) of these states. Measurement of the hyperfine mass splittings between the triplet and singlet states in quarkonium systems is of key importance in understanding the role of spin-spin interactions in quarkonium models and in testing QCD calculations [2]. Theoretical estimates of the mass splitting between the 1S singlet and triplet states vary from 36 to 100 MeV/c\(^2\) [3].

In this Letter, we report the observation of the radiative transition \( Y(3S) \rightarrow \gamma \eta_b(1S) \), where the \( \eta_b(1S) \), hereafter referred to as the \( \eta_b \), is the pseudoscalar partner of the triplet state \( Y(1S) \), and corresponds to the ground state of the bottomonium system. Theoretical predictions of the decay branching fraction range from 1 to \( \times 10^{-4} \) [3], where the unknown \( \eta_b \) mass is a major source of the uncertainties. The current limit from the CLEO III experiment, \( B[Y(3S) \rightarrow \gamma \eta_b] < 4.3 \times 10^{-4} \) at 90% confidence level, is based on 1.39 fb\(^{-1}\) of \( Y(3S) \) data [4].

The data sample used in this study was collected with the BABAR detector [5] at the PEP-II asymmetric-energy \( e^+e^- \) storage rings. It consists of 28.0 fb\(^{-1}\) of integrated luminosity collected at a \( e^+e^- \) center-of-mass (c.m.) energy of 10.355 GeV, corresponding to the mass of the \( Y(3S) \) resonance. Additional samples of 2.4 and 43.9 fb\(^{-1}\) were collected 30 MeV below the \( Y(3S) \) [below-\( Y(3S) \)] and 40 MeV below the \( Y(4S) \) [below-\( Y(4S) \)] resonances, respectively, and are used for background and calibration studies. The trajectories of charged particles are reconstructed using a combination of five layers of double-sided silicon strip detectors and a 40-layer drift chamber, all operated inside the 1.5-T magnetic field of a superconducting solenoid. Photons are detected using a CsI(Tl) electromagnetic calorimeter (EMC), which is also inside the coil. The energy resolution for photons varies from 2.9% (at 600 MeV) to 2.5% (at 1400 MeV).

The signal for \( Y(3S) \rightarrow \gamma \eta_b \) is extracted from a fit to the inclusive photon energy spectrum in the c.m. frame. Any reference to photon energy hereafter will be in the c.m. frame, unless otherwise noted.

The monochromatic photon from the decay appears as a peak on top of a smooth nonpeaking background from continuum \( (e^+e^- \rightarrow q\bar{q}) \) with \( q = u, d, s, c \) events and bottomonium decays. Two other processes produce peaks in the photon energy spectrum close to the signal region. Double radiative decays \( Y(3S) \rightarrow \gamma \chi_{bJ}(2P), \chi_{bJ}(2P) \rightarrow \gamma Y(1S), J = 0, 1, 2 \) produce a broad peak centered at 760 MeV due to photons from decays of the \( \chi_{bJ}(2P) \) states. The peaks from the three \( \chi_{bJ}(2P) \) transitions appear merged due to photon energy resolution and the Doppler broadening that arises from the motion of the \( \chi_{bJ}(2P) \) in the c.m. frame. This \( \chi_{bJ}(2P) \) photon peak is well separated from the signal region of interest (around \( E_\gamma = 900 \) MeV). We use the peak as a tool to verify the optimization of the selection criteria and to determine signal reconstruction efficiencies and the absolute photon energy scale. The other process leading to a peak near 860 MeV in the photon energy spectrum is the radiative production of the \( Y(1S) \) via initial state radiation (ISR) \( e^+e^- \rightarrow \gamma_{\text{ISR}} Y(1S) \). Knowledge of the magnitude and photon energy line shape of this background is crucial in extracting the \( \eta_b \) signal.

We employ a simple set of selection criteria to suppress the backgrounds while retaining a high signal efficiency. Decays of the \( \eta_b \) via two gluons, expected to be a large component of its decay modes, have high track multiplicity. Hadronic events are selected by requiring four or more charged tracks in the event and that the ratio of the second to zeroth Fox-Wolfram moments [6] be less than 0.98.

Photon candidates are required to be isolated from all charged tracks. To ensure that their shapes are consistent with an electromagnetic shower, the lateral moments [7] are required to be less than 0.55. The signal photon candidate is required to lie in the central angular region of the EMC, \( -0.762 < \cos(\theta_{\gamma,\text{LAB}}) < 0.890 \), where \( \theta_{\gamma,\text{LAB}} \) is the angle between the photon and the beam axis in the laboratory frame. This requirement ensures high reconstruction efficiency and good energy resolution, and reduces the contributions of ISR photons from \( e^+e^- \rightarrow \gamma_{\text{ISR}} Y(1S) \) events.

Because of the fact that there is no preferred direction in the decay of the spin-zero \( \eta_b \), the correlation of the direction of the photon momentum in the c.m. frame with the thrust axis [8] of the \( \eta_b \) is small. In contrast, there is a strong correlation between the photon direction and thrust axis in continuum events. The thrust axis is computed with all charged tracks and neutral calorimeter clusters in the event, with the exception of the signal photon candidate. We require \( |\cos(\theta_T)| < 0.7 \) to reduce continuum background, where \( \theta_T \) is the angle between the thrust axis and the signal photon candidate in the c.m. frame.

Photons from \( \pi^0 \) decays are one of the main sources of background. A signal photon candidate is rejected if it combines with another photon in the event to form a \( \pi^0 \) candidate within 15 MeV/c\(^2\) of the nominal \( \pi^0 \) mass. To maintain high signal efficiency, we require the second photon of the \( \pi^0 \) candidate to have an energy in the laboratory frame greater than 50 MeV.

The above-mentioned selection criteria were chosen by optimizing the \( S/\sqrt{B} \) ratio between the expected signal yield \( (S) \) and the background \( (B) \). The signal sample in the optimization is provided by a detailed Monte Carlo (MC) simulation [9]. Since no reliable event generators exist to simulate the background photon distribution, especially from bottomonium decays, a small fraction (9%) of the \( Y(3S) \) data is used in the optimization to model the background in the region \( 0.85 < E_\gamma < 0.95 \) GeV. To avoid potential bias, these data are not used in the final fit of the photon energy spectrum. This optimization procedure,
when applied to the $\chi_{bJ}(2P)$ yield in data in place of the simulated signal, yields the same optimal selection criteria. The final reconstruction efficiency evaluated from the simulated signal MC events is 37%.

The remaining $Y(3S)$ data used for the analysis has an integrated luminosity of 25.6 fb$^{-1}$, which corresponds to (109 ± 1) million $Y(3S)$ events.

To extract the $\eta_b$ signal, we perform a binned maximum likelihood fit of the $E_\gamma$ spectrum with $0.5 < E_\gamma < 1.1$ GeV with four components: nonpeaking background, $\chi_{bJ}(2P) \rightarrow \gamma Y(1S)$, $\gamma_{ISR} Y(1S)$, and the $\eta_b$ signal.

The nonpeaking background is parametrized by the following probability density function (PDF), $f(E_\gamma) = A(C + \exp(-\alpha E_\gamma - \beta E_\gamma^2))$.

The form of the $\chi_{bJ}(2P)$ PDF is complicated by the presence of Doppler broadening. Crystal Ball (CB) functions [10] are used as phenomenological PDFs for the three $\chi_{bJ}(2P) \rightarrow \gamma Y(1S)$ shapes. The CB function is a Gaussian modified to have an extended, power-law tail on the low (left) side. The relative rates and peak positions of the $\chi_{bJ}(2P)$ components are fixed to their world-averaged (PDG) values [11].

The PDF of the peaking background from ISR $Y(1S)$ production is parametrized as a CB function form whose parameters are determined from simulated events. To estimate the rate of this continuum component in $Y(3S)$ data, we use the below-$Y(3S)$ and below-$Y(4S)$ data. Figure 1 shows the $E_\gamma$ distribution in the below-$Y(4S)$ data, after applying the selection criteria and subtracting the nonpeaking background. The fit with a CB function yields 35 800 ± 1600 events. Extrapolating the cross section to the $Y(3S)$ energy and correcting for the luminosity ratio and the small difference in detection efficiency, the ISR photon background contribution in the final analysis is estimated to be 25 200 ± 1700 events. The error includes systematic uncertainties. This is consistent with and more precise than the rate estimated using the below-$Y(3S)$ data.

In the final fit of the whole $E_\gamma$ distribution to the $\eta_b$ signal, all parameters of the $\chi_{bJ}(2P)$ peak and the ISR $Y(1S)$ PDFs are fixed to the values from the fits described above.

The $\eta_b$ signal PDF is a nonrelativistic Breit-Wigner function convolved with a CB function to account for the experimental $E_\gamma$ resolution. The CB parameters are determined from signal MC simulations with the $\eta_b$ width set to zero. Since the width of the $\eta_b$ is not known, we have chosen a nominal value of 10 MeV/$c^2$ for the width. Theoretical predictions based on the expected ratio of the two-photon and two-gluon widths range from 4 to 20 MeV [12]. The free parameters in the fit are the $\eta_b$ peak position and signal yield, the $\chi_{bJ}(2P)$ yield, and all of the nonpeaking background PDF parameters.

Figure 2(a) shows the photon energy spectrum and the fit result. The nonpeaking background is dominant with only the prominent $\chi_{bJ}(2P)$ peak visible. In Fig. 2(b) we show the detail of the signal region, after subtracting the nonpeaking background. The line shapes of the three peaking components, $\chi_{bJ}(2P)$, ISR $Y(1S)$, and the $\eta_b$ signal are clearly visible. The $\chi^2$ per degree of freedom from the fit is 147/113 = 1.3. Finally Fig. 2(c) shows the data points with all components except the $\eta_b$ signal subtracted, overlaid with the $\eta_b$ signal PDF. The fitted $\eta_b$ signal yield is 19 200 ± 2000 ± 2100 events, where the first error is statistical and the second systematic. A total systematic uncertainty of 11% is estimated by varying the Breit-Wigner width in the $\eta_b$ PDF to 5, 15, and 20 MeV, setting the ISR $Y(1S)$ component to ±1σ of the nominal rate, and varying the PDF parameters fixed in the fit by ±1σ. The largest contribution (10%) is from the $\eta_b$ width variation.

The $\eta_b$ signal significance is estimated using the ratio log ($L_{\text{max}}/L_0$), where $L_{\text{max}}$ and $L_0$ are the likelihood values obtained from the nominal fit and from a fit with the $\eta_b$ PDF removed, respectively. Fits have been performed where the parameters entering the systematic uncertainties have been varied within their errors. Data have then been fitted with all parameters simultaneously moved by 1 standard deviation in the direction of lower significance. This conservative approach yields a signal significance greater than 10 standard deviations.

As a cross check, we also perform a fit where the yield of the ISR $Y(1S)$ component is left free, and we obtain 24 800 ± 2300 events for this component. This is consistent with the estimate using the below-$Y(4S)$ data and provides an important validation of the $\chi_{bJ}(2P)$ line shape.

![Figure 1](https://example.com/figure1.png)

**FIG. 1.** Inclusive photon energy spectrum in the below-$Y(4S)$ data, with the nonpeaking background subtracted. The peak at 1.03 GeV is from the ISR process $e^+ e^- \rightarrow \gamma_{ISR} Y(1S)$. The superimposed histogram corresponds to a fit with a CB function.
an additional systematic uncertainty of 1.3 MeV from the fit variations described above, we obtain a value of $E_\gamma = 921.2^{+2.1}_{-2.8} \pm 2.4$ MeV for the $\eta_b$ signal.

The $\eta_b$ mass derived from the $E_\gamma$ signal is $M(\eta_b) = 9388.9^{+3.1}_{-2.3} \pm 2.7$ MeV/$c^2$. Using the PDG value of 9460.3 $\pm$ 0.3 MeV/$c^2$ for the $Y(1S)$ mass, we determine the $Y(1S)$-$\eta_b$ mass splitting to be $71.4^{+2.1}_{-1.3} \pm 2.7$ MeV/$c^2$.

The value we measure for the splitting is larger than most predictions based on potential models [2], but reasonably in agreement with predictions from lattice calculations [13]. The mass splitting between the $Y(1S)$ and the $\eta_b(1S)$ is a key ingredient in many theoretical calculations. The precision of our measurement will allow, among others, a more precise determination of the lattice spacing [13] and new precision determinations of $\alpha_s$ [14].

We estimate the branching fraction by correcting the signal yield with the reconstruction efficiency ($\epsilon$) from simulated signal MC events, and then dividing it by the number of $Y(3S)$ events in the data sample. The branching fraction of the decay $Y(3S) \rightarrow \gamma \eta_b$ is found to be $(4.8 \pm 0.5 \pm 1.2) \times 10^{-4}$, where the first uncertainty is statistical and the second systematic. The systematic uncertainty of 25% comes from uncertainties in the signal yield (11%) and $\epsilon$ (22%). The latter is obtained by comparing the yield of $\gamma_b(2P)$ in data to the number of expected events, which is calculated from the known branching fractions [11], the number of $Y(3S)$ events, and MC reconstruction efficiency of $\gamma_b(2P)$. They show a 13% discrepancy, but are consistent within the errors. We assign the full difference to the systematic uncertainty. A total uncertainty in $\epsilon$ is obtained, after adding the uncertainties in the $\gamma_b(2P)$ branching fractions (18%).

In conclusion, we have observed, with a significance of 10 standard deviations, the radiative decay of the $Y(3S)$ to a narrow state lying slightly below the $Y(1S)$. The most likely interpretation of the signal peak is the $Y(3S)$ transition to the bottomonium ground state, although other hypotheses, such as a radiative transition to a light Higgs boson, are not excluded. Under the bottomonium interpretation, this is the first evidence for the $\eta_b$ bottomonium state, the pseudoscalar partner of the $Y(1S)$. The mass of the $\eta_b$ is $9388.9^{+3.1}_{-2.3} \pm 2.7$ MeV/$c^2$, which corresponds to a mass splitting between the $Y(1S)$ and the $\eta_b$ of $71.4^{+2.1}_{-1.3} \pm 2.7$ MeV/$c^2$. The estimated branching fraction of the decay $Y(3S) \rightarrow \gamma \eta_b$ is found to be $(4.8 \pm 0.5 \pm 1.2) \times 10^{-4}$.

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues, and for the substantial dedicated effort from the computing organizations that support BABAR. We thank Bob McElrath and Michael Peskin for helpful discussions. The collaborating institutions wish to thank SLAC for its support and kind hospitality. This work is supported by DOE and NSF (USA), NSERC (Canada), CEA and CNRS-IN2P3.
